What interactions are sufficient to simulate arbitrary quantum dynamics in a composite quantum system? It has been shown that all two-body Hamiltonian evolutions can be simulated using *any* fixed two-body entangling n -qubit Hamiltonian and fast local unitaries. By *entangling* we mean that every qubit is coupled to every other qubit, if not directly, then indirectly via intermediate qubits. We extend this study to the case where interactions may involve more than two qubits at a time. We find necessary and sufficient conditions for an arbitrary n -qubit Hamiltonian to be *dynamically universal*, that is, able to simulate any other Hamiltonian acting on n qubits, possibly in an inefficient manner. We prove that an entangling Hamiltonian is dynamically universal if and only if it contains at least one coupling term involving an *even* number of interacting qubits. For *odd* entangling Hamiltonians, i.e., Hamiltonians with couplings that involve only an odd number of qubits, we prove that dynamic universality is possible on an encoded set of $n - 1$ logical qubits. We further prove that an odd entangling Hamiltonian can simulate any other odd Hamiltonian and classify the algebras that such Hamiltonians generate. Thus, our results show that up to local unitary operations, there are only two fundamentally different types of entangling Hamiltonian on n qubits. We also demonstrate that, provided the number of qubits directly coupled by the Hamiltonian is bounded above by a constant, our techniques can be made efficient.

I. INTRODUCTION

One of the main goals of quantum information science is to characterize the physical resources that are *universal* for quantum computation and simulation. Recently, the role of entangling quantum dynamics has been studied in depth, and it has been shown that a fixed two-body entangling Hamiltonian evolution acting on a system, plus the ability to intersperse local unitary operations, can be used to efficiently simulate any other two-body Hamiltonian and hence is universal for quantum computation (see, for example [1, 2, 3, 4, 5, 6, 7, 8, 9, 10], and references therein.)

We extend this study to Hamiltonians containing interaction terms involving more than two qubits at a time. Using results from quantum control theory, we determine what dynamics can be simulated with an *arbitrary* fixed n -qubit Hamiltonian, and complete local control in the form of one-qubit unitary operations. In particular, we derive a simple criterion determining which Hamiltonians are universal given local unitary operations.

In contrast to two-body entangling Hamiltonians, which are always universal given local operations [1, 2, 3, 4, 5, 6, 7, 8, 9, 10], we will see that not all many-body entangling Hamiltonians are universal, given arbitrary one-qubit operations as the only additional resource. This was previously noted for a specific example by Vidal and Cirac [9]. Thus, unlike two-body Hamiltonians, many-qubit entangling Hamiltonians are not all equivalent up to local operations. The situation is somewhat analogous to the study of multi-party entangled states, where it has been shown that there exist different types of entanglement, inequivalent up to local operations and classical communication [11, 12, 13] (LOCC). For example, it is now well known that the “GHZ” and “W” states are not equivalent up to LOCC.

Consider the following illustrative example. Suppose we are given a Hamiltonian acting on three qubits, $H = X \otimes X \otimes I + I \otimes X \otimes X$, where X is the usual Pauli σ_x operator. Then, if we can perform arbitrary local unitary operations on each of the qubits, it has been shown in [1, 2, 3, 4, 5] that it is possible to simulate any other Hamiltonian interaction on three qubits, such as $H' = X \otimes X \otimes X$. We call such a Hamiltonian *universal*. On the other hand, given H' and arbitrary local unitaries, it turns out that it is not possible to simulate H , and thus H' is not universal. A proof of this is given in [9]; both these results will also follow from the general results given in this paper.

We address the problem of universality in full generality by giving a necessary and sufficient condition for a Hamiltonian to be universal. Our condition is dependent only on simple properties of the Hamiltonian's decomposition into tensor products of Pauli operators. The proof of this condition is constructive, in the sense that it provides, in principle, an algorithm for using a universal Hamiltonian to simulate any other interaction. However, the techniques used in our construction are not especially practical, especially in the presence of noise, and it remains to be seen if more practical constructions are possible.

In addition to our criterion for universality, we also examine what can be done when a given Hamiltonian is not universal. In particular, we show that there always exists a simple encoding scheme to make these Hamiltonians universal.

Let us make a more precise statement of our results. Suppose we are given a Hamiltonian H acting on n qubits, which can be written uniquely in terms of its Pauli operator expansion

$$H = \sum_{j_1, \dots, j_n=0}^3 h_{j_1 \dots j_n} \sigma_{j_1} \otimes \dots \otimes \sigma_{j_n}, \quad (1)$$

where the $h_{j_1 \dots j_n}$ are real numbers and $\sigma_1, \sigma_2, \sigma_3$ are the Pauli sigma matrices X, Y, Z , respectively, with $\sigma_0 \equiv I$ the identity. We say that a subset S of the qubits is *coupled* by this Hamiltonian if there is a non-zero term in H coupling those specific qubits.

When is H universal? An obvious condition is that the set of qubits coupled by H must be *connected*. That is, it should not be possible to partition the qubits into non-trivial sets, S and $\bar{S}$, such that every term in the Pauli operator expansion couples either a subset of S or a subset of $\bar{S}$. If this were the case then H could not be used to generate entanglement between the qubits in S and the qubits $\bar{S}$, and thus would not be universal. We say that a Hamiltonian connecting all the qubits in this way is an *entangling* Hamiltonian. Note that this definition may be restated in the language of graph theory: if qubits correspond to vertices in a hypergraph, and couplings between qubits correspond to hyper-edges, then the condition that the Hamiltonian is entangling corresponds to the condition that the hypergraph is connected.

With this background, our main results are easily stated. Our first result is that an entangling Hamiltonian and local unitaries is universal if and only if the Pauli operator expansion for the Hamiltonian contains a term coupling an even number of qubits. This result provides a simple, easily checkable criterion to determine whether or not a Hamiltonian is universal. Returning to our previous examples $H = X \otimes X \otimes I + I \otimes X \otimes X$ and $H' = X \otimes X \otimes X$, this criterion tells us that H is universal when assisted by local unitaries, while H' is not, in agreement with the earlier claims.

Our second result concerns what happens when the Pauli operator expansion contains only odd terms, and

thus is not universal. We say that such a Hamiltonian is an *odd* entangling Hamiltonian. We will prove that an odd entangling Hamiltonian acting on n qubits is capable of simulating any other odd Hamiltonian acting on those qubits. Thus, the odd entangling Hamiltonians are a fungible physical resource, since having any one is equivalent to having any other, up to local unitary operations. Furthermore, we show that an odd Hamiltonian, together with local unitaries, generates either the simple Lie algebra $\mathfrak{so}(2^n)$ or $\mathfrak{sp}(2^n)$, depending on the number of qubits n that are connected by the Hamiltonians.

Our third result also concerns odd Hamiltonians. We prove that, with appropriate encoding, an odd entangling Hamiltonian and local unitaries is universal on a set of $n - 1$ logical qubits. Thus, there is not too great a loss in space efficiency when one attempts to use such a Hamiltonian to simulate an arbitrary interaction.

Our results thus completely classify what can be achieved with an n -qubit Hamiltonian and local unitary operations. They demonstrate that there are essentially only two types of Hamiltonians up to local unitary operations: those whose Pauli operator expansion contains only odd parity terms, and those with at least one even term.

An important caveat to our results concerns *efficiency*. When we state that a set of interactions is *universal* on a set of qubits, we mean simply that those interactions can be used to simulate any other interaction, without any claim as to whether the simulation procedure is efficient, or otherwise. We will say such a set of interactions is *dynamically universal*. By contrast, in the context of quantum computing, a set of resources is said to be *universal for quantum computation* if it can be used to simulate a standard set of universal gates, such as the controlled-NOT and one-qubit unitary gates, *with an overhead that is at most polynomial in the number of qubits*.

Our results thus concern dynamic universality, and do not directly address the question of universal quantum computation. However, some general observations may be made about the efficiency of our constructions. When the number of qubits that are directly coupled by the Hamiltonian is bounded above by some constant k , then our simulation techniques for gates such as the controlled-NOT only incur an overhead polynomial in the total number of qubits. Thus, when the coupling size is bounded, our results give criteria not only for dynamic universality, but also for universal quantum computation. By contrast, when the number of qubits involved in couplings is unbounded, our simulation technique is not polynomial, and thus our results cannot be applied to deduce anything about universal quantum computation. Indeed, we conjecture that the two concepts of universality do not, in general, coincide.

For the remainder of this paper, when we speak of a set of couplings being universal, we mean dynamically universal, unless otherwise stated. The only exception is in Section VI, which contains the proof that when the terms in the Hamiltonian couple only a bounded number

of qubits, our techniques can be made efficient.

What is the significance of our findings? It is tempting to conclude that the main significance is for the design of quantum computers. However, we do not believe our results are especially significant for such questions. Not only are our constructions impractical, but it is an empirical fact that most interactions occurring in nature are two-body interactions, and thus are adequately dealt with by earlier work.

We believe our results are interesting for two other, less obvious, reasons. The first is the intrinsic interest in obtaining general insights into quantum dynamics. The fact that, given local unitary control, there are only two different classes of Hamiltonian evolution, seems to us a significant insight into the complicated space of possible dynamical evolutions. It tells us that dynamics within each of these classes are *fungible* physical resources. In the case of two-party interactions this insight has led to the beginnings of a quantitative theory of the *strength* [14, 15] of dynamical operations, much as the theory of entanglement dilution and concentration [16] led to the quantitative theory of entanglement [17, 18].

An interesting contrast is to the situation with state entanglement, where the multipartite structure is complex and only partially understood. The number of classes of states which are inequivalent under local operations and classical communication (LOCC) is enormous — for four-qubit states, there are already at least 9 inequivalent classes [19]. Our results thus demonstrate that there are no direct analogies between multipartite state entanglement and multipartite entangling dynamics — in fact, the situation is substantially simpler for dynamics than it is for states.

A second reason for interest is possible indirect applications. For example, although four-qubit interactions may not occur in nature, it is certainly the case that interactions involving two objects with four-dimensional state spaces may occur in nature. Such systems can naturally be mapped onto our problem by considering a single four-dimensional system as being, effectively, a system of two qubits. Constructions like this may make our results of interest, at least in principle, for realistic physical systems.

The paper is structured as follows. Section II provides background and definitions. Section III establishes a body of general techniques for simulating one Hamiltonian with another. These techniques are applied in Section IV to prove our first main result, the characterization of when a Hamiltonian is universal, assisted by one-qubit unitaries. Section V studies the non-universal case, proving that any odd entangling Hamiltonian may be used to simulate any other odd Hamiltonian. We then describe an encoded universality scheme that allows an odd entangling n -qubit Hamiltonian to act universally on $n - 1$ qubits, and provide a Lie-algebraic classification of this case. In Section VI we show that our techniques can be made efficient under certain conditions of bounded coupling size, and finally in Section VII we summarize

our results.

II. BACKGROUND AND DEFINITIONS

This section contains definitions and background material for the remainder of the paper. We begin with some notation and definitions, followed by a discussion of what it means to simulate one Hamiltonian with another, and finally we review some previous work on the universality of two-body Hamiltonians.

We now introduce some notational conventions. As stated in the introduction, an arbitrary Hamiltonian H on n qubits can be uniquely written in terms of Pauli operators via the Pauli operator expansion

$$H = \sum_{j_1, \dots, j_n=0}^3 h_{j_1 \dots j_n} \sigma_{j_1} \otimes \dots \otimes \sigma_{j_n}, \quad (2)$$

where the $h_{j_1 \dots j_n}$ are real numbers and $\sigma_1, \sigma_2, \sigma_3$ are the Pauli sigma matrices X, Y, Z , respectively, with $\sigma_0 \equiv I$ the identity. Let the index α denote each different combination $j_1 \dots j_n$ corresponding to non-zero terms in equation (2). So for each non-zero term in the Pauli expansion of H we write $H_\alpha = h_{j_1, \dots, j_n} \sigma_{j_1} \otimes \dots \otimes \sigma_{j_n}$ and thus $H = \sum_\alpha H_\alpha$.

Definition 1. Let C_α denote the set of all Pauli product Hamiltonians that couple the same set of qubits as $H_\alpha = h_{j_1, \dots, j_n} \sigma_{j_1} \otimes \dots \otimes \sigma_{j_n}$, that is $C_\alpha = \{\sigma_{k_1} \otimes \dots \otimes \sigma_{k_n} | k_i = 0 \text{ iff } j_i = 0\}$. We call each set C_α a *coupling set*.

For example if $H_\alpha = X \otimes I \otimes Y \otimes Y$, then C_α is the set of all products of Paulis acting non-trivially on the same qubits, or $\{X \otimes I \otimes X \otimes X, X \otimes I \otimes X \otimes Y, \dots, Z \otimes I \otimes Z \otimes Z\}$.

Definition 2. The set S_α is the set of qubits coupled by H_α , or, equivalently, all elements of C_α .

In the example above $S_\alpha = \{1, 3, 4\}$. Note that different H_α 's can give rise to the same C_α and S_α . We will use the notation $|S_\alpha|$ to denote the number of qubits in the set S_α .

Now, what does it mean to simulate one Hamiltonian with another? If we can approximately induce evolution according to a Hamiltonian H on an arbitrary state $|\psi\rangle$ for an arbitrary time t without actually using H , then we can simulate H , provided the approximation can be made arbitrarily good. This concept of simulation is motivated by quantum computation which uses a universal set of gates to simulate arbitrary unitary evolutions on a set of qubits.

Our approach to the question of whether a Hamiltonian is universal is to exhaustively build up the repertoire of different evolutions simulatable with the Hamiltonian, in such a way that it becomes clear whether or not the repertoire is a universal set of gates.

A first observation is that, given a term $H_\alpha = h_{j_1 \dots j_n} \sigma_{j_1} \otimes \dots \otimes \sigma_{j_n}$ we can simulate xH_α for any real

non-zero x by adjusting the amount of time we evolve according to H_α . Therefore, we can always simulate $\tilde{H}_\alpha \equiv \pm \sigma_{j_1} \otimes \cdots \otimes \sigma_{j_n}$ with the sign given by the sign of $h_{j_1 \dots j_n}$. If it is negative, then we can make it positive by conjugating $\tilde{H}_\alpha$ by a one-qubit unitary U which anticommutes with it. Thus, we can always obtain $\sigma_{j_1} \otimes \cdots \otimes \sigma_{j_n}$. For the remainder of the paper, we will always assume that terms like H_α have this form.

A simple, but important, observation is that, given the ability to evolve according to some Hamiltonian J and to perform a unitary operation U and its inverse $U^\dagger$, we can evolve according to

$$U e^{-iJt} U^\dagger = e^{-iUJU^\dagger t}. \quad (3)$$

That is, we can simulate evolution according to the Hamiltonian $J' = UJU^\dagger$.

This result can be used to show, for example, that given a Pauli product Hamiltonian H_α , we can simulate any other coupling in C_α , simply by performing local changes of basis on each of the qubits to interchange the role of the x, y and z axes. This is done by conjugating by one of the following three rotations:

$$e^{i\frac{\pi}{4}X}, e^{i\frac{\pi}{4}Y}, e^{i\frac{\pi}{4}Z}. \quad (4)$$

Now, suppose we can evolve according to two Hamiltonians J_1 and J_2 . Then for small times Δ the following identity holds approximately:

$$e^{-iJ_1\Delta} e^{-iJ_2\Delta} \approx e^{-i(J_1+J_2)\Delta}. \quad (5)$$

That is, we can simulate evolution according to the Hamiltonian $J_1 + J_2$. Equation (5) is important because it tells us that if we are able to evolve a system according to a set of different Hamiltonians, then it is possible to simulate arbitrary linear combinations of elements of the set. We will treat this identity as though it is exact for the remainder of the paper. This is justified for small Δ . (See [1] for an analysis of the errors induced by this approximation, and the overhead required to reduce them). The above identities are used extensively in this paper, as they were in [1, 2, 3, 4, 5, 6, 7, 8, 9, 10].

It is also possible to simulate the commutator of two Hamiltonians [20, 21], since

$$e^{-iJ_1\Delta} e^{iJ_2\Delta} e^{iJ_1\Delta} e^{-iJ_2\Delta} \approx e^{-i([J_1, J_2])\Delta^2} \quad (6)$$

for small Δ . The error in this approximation is of order Δ^3 , and can be made insignificant by choosing Δ sufficiently small. This completes the basic set of tools that we use to build up our repertoire of simulatable Hamiltonians. The reason for this is that given a set of Hamiltonians $L = \{J_1, \dots, J_\zeta\}$ the set of all simulatable Hamiltonians is given by the Lie algebra generated by the set L [22] which can in turn be generated with linear combinations and i times commutators of elements from L .

We can thus refine the central question of this paper to be: how does the structure of the given Hamiltonian H determine the Lie algebra that can be generated by H and arbitrary one-qubit evolutions? This is the question that we address in the remainder of this paper.

III. METHODS

In the previous section we introduced some notation and basic tools. This section is concerned with building up more sophisticated simulation methods for the proofs of our main results, in later sections. In particular, there are two interesting simulation ideas — term isolation and commutator restriction — that we will examine in separate subsections. These ideas may be more fully described as follows:

A. Term isolation: Given that we can simulate H and perform arbitrary local unitaries, we can simulate an arbitrary term H_α in the expansion of H . Recall that we write $H = \sum_\alpha H_\alpha$ where each H_α is a Pauli product Hamiltonian.

B. Commutator restrictions: We examine the restrictions placed on the simulation of commutators of coupling terms in H .

A. Term isolation

In this section, we show that given H we can simulate each term H_α in H using one-qubit unitaries and the composition identities given in equations (3) and (5). Thus the capacity to simulate H is equivalent up to one-qubit unitaries to being able to simulate each H_α .

For simplicity in the proof we now note that we can use one-qubit unitaries to simulate the Hamiltonian $H^{(1)} = V_1 \otimes \cdots \otimes V_n H V_1^\dagger \otimes \cdots \otimes V_n^\dagger$ where the one-qubit unitaries $V_1, \dots, V_n$ are chosen so that the term H_α has all X and Y operators in its expansion taken to Z and all Z and I operators left alone. Thus in the Hamiltonian $H^{(1)}$ every $\sigma_j \neq I$ in H_α is now Z . Let us denote this term in $H^{(1)}$ by H_{α_Z} . This term, equivalent to H_α , is the term that we wish to isolate. From now on we use the convention that the superscript on a simulated Hamiltonian indicates a step in the algorithm, so $H^{(j)}$ would be the Hamiltonian simulated after the j^{th} step. We will also use subscripts on non-trivial one-qubit operators to indicate which qubit they are acting on. For example, X acting on the third qubit is written $X_3 \equiv I \otimes I \otimes X \otimes I \otimes \cdots$.

We now use $H^{(1)}$ to simulate $H^{(2)} = Z_1 H^{(1)} Z_1 + H^{(1)}$. Noting that $ZZZ = Z$, $ZXZ = -X$ and $ZYZ = -Y$, we see that the term H_{α_Z} is replaced in $H^{(2)}$ by $2H_{\alpha_Z}$, but any term in $H^{(1)}$ which has X or Y acting on the first qubit is cancelled out. We then simulate $H^{(3)} = Z_2 H^{(2)} Z_2 + H^{(2)}$ and so on until we obtain $H^{(n+1)} = Z_n H^{(n)} Z_n + H^{(n)}$. In this Hamiltonian, H_{α_Z} has been replaced by $2^n H_{\alpha_Z}$ and it consists only of terms containing Z or I .

Now we wish to remove all interactions that act on qubits outside of S_α . We do this by conjugating with X on each of these qubits. If H_{α_Z} has an I acting on the q^{th} qubit, then we simulate $H^{(n+2)} = X_q H^{(n+1)} X_q + H^{(n+1)}$. This takes $2^n H_{\alpha_Z}$ to $2^{n+1} H_{\alpha_Z}$ and cancels any terms that

have a Z acting on the q^{th} qubit. Let $k \equiv |S_\alpha|$. Since there are $n - k$ qubits upon which H_{α_Z} doesn't act, if we perform this style of simulation $n - k$ times on different qubits, then we will have removed all interactions acting on qubits outside of S_α . So the simulated Hamiltonian $H^{(2n-k+1)}$ has interactions that only act on subsets of S_α , and H_{α_Z} has become $2^{2n-k}H_{\alpha_Z}$.

At this point, we wish to eliminate all remaining terms except H_{α_Z} . Denote one of these undesirable terms by H_{β_Z} . We know that H_{β_Z} couples a set of qubits S_β that is strictly contained in S_α . Thus, there must be some qubit q which is in S_α and not in S_β . Noting that $X_p X_q$ commutes with $Z_p Z_q$ but anticommutes with $Z_p I_q$ for $p \neq q$, we see that conjugating by $X_p X_q$ leaves H_{α_Z} invariant but takes H_{β_Z} to $-H_{\beta_Z}$ if we choose p to be in S_β . Thus, if we simulate $H^{(2n-k+2)} = X_p X_q H^{(2n-k+1)} X_p X_q + H^{(2n-k+1)}$ we eliminate H_{β_Z} . Iterating this procedure for every combination of p and q in S_α , we can eliminate every remaining undesirable term. There are $\binom{k}{2}$ such possible combinations, so we finally obtain

$$H^{(2n-k+1+\binom{k}{2})} = 2^{2n-k+\binom{k}{2}} H_{\alpha_Z}. \quad (7)$$

Summarizing, we can isolate any term in H , and thus can simulate all elements of C_α for every H_α appearing in H , as well as all linear combinations of the elements of C_α .

We note in passing a group-theoretic interpretation [23, 24] of the term isolation procedure described above. A particular term H_α that we wish to isolate forms, along with the identity, an order two group $\mathcal{G}$ which is a subgroup of the full Pauli group $\mathcal{P}$ on our system. In particular H_α and I are a representation of this subgroup $\mathcal{G}$. Denote the commutant of $\mathcal{G}$ in $\mathcal{P}$ (the set of all group elements in $\mathcal{P}$ which commute with $\mathcal{G}$) as $\mathcal{G}'$. If we map the elements of $\mathcal{G}'$ to Pauli operators, then we have a faithful representation of $\mathcal{G}'$. Let us denote the elements of this representation by $D(g')$, where $g' \in \mathcal{G}$. From Schur's lemma it then follows that by averaging over all elements in this representation of $\mathcal{G}'$ we obtain only elements in the representation of $\mathcal{G}$ given by H_α and I :

$$\frac{1}{|\mathcal{G}'|} \sum_{g' \in \mathcal{G}'} D(g') H D(g')^\dagger = aI + bH_\alpha \quad (8)$$

for some constants a and b . Thus we can isolate a term by performing the appropriate group average over the commutant subgroup. In fact, since $\mathcal{G}$ is abelian, we can average over elements in $\mathcal{G}'$ which are not in $\mathcal{G}$. The term isolation procedure we described above is a concrete realization of this group average.

B. Commutator restrictions

We now turn to the simulation of Hamiltonians using commutators, focusing on the possible forms of Hamil-

tonians simulated in this manner. The restrictions we obtain will be vital for the results of the next section.

Consider two different elements of the coupling set C_α , H_α and $H_{\alpha'}$. It is straightforward to verify from the commutation relations for the Pauli matrices that *the commutator $[H_\alpha, H_{\alpha'}]$ is non-zero if and only if there is an odd number of locations in S_α where the couplings H_α and $H_{\alpha'}$ differ*. For example, consider the commutator of $H_\alpha = X \otimes X \otimes X$ and $H_{\alpha'} = Y \otimes X \otimes Y$, both of which couple the same qubits:

$$\begin{aligned} i[H_\alpha, H_{\alpha'}] &= i(XY \otimes I \otimes XY - YX \otimes I \otimes YX) \\ &= i(XY \otimes I \otimes XY - XY \otimes I \otimes XY) = 0. \end{aligned} \quad (9)$$

We see that in this case an even number — two — of the qubits are acted on by different Paulis, and so the commutator is zero. However if $H_{\alpha'} = Y \otimes X \otimes X$, the commutator is non-zero, indeed it is $i[H_\alpha, H_{\alpha'}] = -2Z \otimes I \otimes I$. We see from this example that given an initial coupling, we can generate terms which couple a different set of qubits.

Suppose now that C_α and C_β are two different coupling sets. If they act on nonoverlapping sets of qubits, then any commutator between an element of C_α and an element of C_β will always be zero. The commutators between two particular Hamiltonians H_α and H_β depend only on their actions on qubits in the intersection of the sets S_α and S_β . Recall that the commutator of two terms is nonzero if there is an odd number of pairs that disagree. Thus H_α and H_β must differ on an odd number of qubits from the intersection of S_α and S_β in order to have a nonzero commutator. To summarize, a commutator of Hamiltonians from C_α and C_β can generate a Hamiltonian coupling a set of qubits S_γ precisely when S_γ is in $S_\alpha \cup S_\beta$, S_γ contains an odd number of qubits from $S_\alpha \cap S_\beta$, and S_γ contains all the qubits from both S_α and S_β which are not in $S_\alpha \cap S_\beta$.

This becomes clearer with an example. Suppose $H_\alpha = X \otimes X \otimes X \otimes X$ and $H_\beta = Z \otimes X \otimes X \otimes I$. We find that the commutator is $i[H_\alpha, H_\beta] = -2Y \otimes I \otimes I \otimes X$. So we see that we have simulated a two-qubit entangling Hamiltonian, with a four- and a three-qubit coupling.

Combining all of our results about simulation so far, we see that given $H = \sum_\alpha H_\alpha$ and arbitrary one-qubit unitaries, we can isolate any term H_α . This can then be used to simulate any Hamiltonian coupling the same set of qubits. All of these terms can be combined in arbitrary linear combinations. Finally, we can use pairs of couplings C_α and C_β to simulate a coupling on a different set of qubits S_γ when the conditions stated above hold. The coupling C_γ can be added to our repertoire of simulatable couplings, and can be used in turn to generate new couplings. How many different couplings are there? Since we assume that there is a finite number of qubits n there are no more than 2^n different coupling sets, so the process of generating new couplings and adding them to the repertoire must terminate.

Once all of the simulatable couplings have been enumerated, the complete set of simulatable Hamiltonians consists of those whose Pauli operator expansion contains only terms that belong to one of the simulatable couplings. Of course, this procedure of exhaustive enumeration for determining which Hamiltonians are simulatable is not especially efficient or insightful. In the next section we provide a surprisingly simple procedure that enables us to determine when a Hamiltonian is universal.

IV. STRUCTURE OF SIMULATED COUPLINGS AND DYNAMIC UNIVERSALITY

In the previous section we identified various simulation methods for Hamiltonians acting on qubits. In this section we use these methods to classify which many-qubit Hamiltonians are universal given local unitary operations, assuming throughout that the Hamiltonians under consideration are entangling. In order to find this classification we use properties of the Pauli operator expansion of a qubit Hamiltonian as given by equation (2). In particular, we will see that the parities of the couplings in this expansion determine whether or not H is universal.

We know from subsection III A that given $H = \sum_{\alpha} H_{\alpha}$ and local unitaries we can simulate any particular coupling term H_{α} . If we had as our base set of operations each H_{α} in the expansion of H , and local unitaries, we could simulate H . Thus, having H and local unitaries is equivalent to having $\{H_{\alpha}\}$ and local unitaries. In this section we focus on the simulating capacity of particular coupling terms H_{α} as this will be sufficient for analyzing the universality of H .

In section II we defined the coupling set C_{α} as being the complete set of Pauli product Hamiltonians that couple the set of qubits S_{α} . We also noted that a single element of C_{α} and arbitrary one-qubit unitary control generates all elements of C_{α} . In this section we will often use the coupling set C_{α} and any single element of that set interchangeably. For convenience, we write LU to represent all local unitaries, that is, products of one-qubit unitaries. We also define the *parity* of a Pauli-product Hamiltonian H_{α} to be odd if it acts non-trivially on an odd number of qubits, or, equivalently, if S_{α} contains an odd number qubits. Otherwise, we say that H_{α} has even parity. We will see that dynamic universality of H is completely determined by the parities of the terms in H .

For convenience, we restate a previous result that we will use frequently.

Theorem 1 (Bipartite Hamiltonian theorem [1, 2, 3, 4, 5]). *Suppose H , acting on n qubits, has only one- and two-qubit terms in its Pauli-product expansion, and that H is entangling, i.e., all n qubits are connected, possibly indirectly, by the terms in H . Then H , together with local unitaries, is universal for quantum computation on n qubits.*

We now prove a series of lemmas leading to our first new theorem.

Lemma 1. *If Hamiltonians H_{α} and H_{β} act on sets of qubits S_{α} and S_{β} such that $S_{\beta} \subset S_{\alpha}$ and $|S_{\alpha}| = |S_{\beta}| + 1$ then the set $\{H_{\alpha}, H_{\beta}, LU\}$ is universal on S_{α} .*

Before giving the proof, consider the example $H_{\alpha} = X \otimes X \otimes X \otimes X$ and $H_{\beta} = Y \otimes X \otimes X \otimes I$. Their commutator is

$$i[H_{\alpha}, H_{\beta}] = -2Z \otimes I \otimes I \otimes X \quad (10)$$

which means that we can simulate arbitrary couplings between qubits 1 and 4. On the other hand, the commutator of $X \otimes Y \otimes X \otimes I \in C_{\beta}$ with H_{α} generates a coupling between qubits 2 and 4. Similarly, we can couple qubits 3 and 4. Using Theorem 1 we see that $\{H_{\alpha}, H_{\beta}, LU\}$ is universal on the set of qubits S_{α} .

Proof: Assume without loss of generality that the qubits are numbered so that the first $n - 1$ of them are in S_{β} . Then $X^{\otimes n} \in C_{\alpha}$ and $X^{\otimes n-2} \otimes Y \otimes I \in C_{\beta}$, where Y acts on the $(n - 1)^{\text{th}}$ qubit. We can simulate the commutator of these Hamiltonians

$$i[X^{\otimes n}, X^{\otimes n-2} \otimes Y \otimes I] = -2I^{\otimes n-2} \otimes Z \otimes X. \quad (11)$$

and thus we can couple the $(n - 1)^{\text{th}}$ and n^{th} qubits. We can perform similar simulations where Y acts on each qubit in the range 1 to $n - 1$. This generates two-qubit couplings connecting all of S_{α} , and Theorem 1 implies that $\{H_{\alpha}, H_{\beta}, LU\}$ is universal on S_{α} . $\square$

Lemma 2. *If a Hamiltonian H_{α} has even parity then $\{H_{\alpha}, LU\}$ is universal on S_{α} .*

Proof: This result follows almost immediately from Lemma 1. Let $n = |S_{\alpha}|$. Notationally, it will be convenient to omit qubits outside the set S_{α} in the following; in all cases there is an implied identity action on the omitted qubits. Since $X^{\otimes n} \in C_{\alpha}$ and $Y^{\otimes n-1} \otimes X \in C_{\alpha}$, we can simulate the commutator

$$i[X^{\otimes n}, Y^{\otimes n-1} \otimes X] = 2i(iZ)^{\otimes n-1} \otimes I \quad (12)$$

as $n - 1$ is an odd number. Since $2i(iZ)^{\otimes n-1} \otimes I$ acts on $n - 1$ qubits, Lemma 1 allows us to conclude that $\{H_{\alpha}, LU\}$ is universal on S_{α} . $\square$

Corollary 1. *If H_{α} and H_{β} both have even parity and $S_{\alpha} \cap S_{\beta} \neq \emptyset$, then $\{H_{\alpha}, H_{\beta}, LU\}$ is universal on $S_{\alpha} \cup S_{\beta}$.*

Proof: Lemma 2 tells us that H_{α} is universal on S_{α} and H_{β} is universal on S_{β} . Since they have a non-empty intersection, they can simulate a set of two-qubit Hamiltonians connecting every qubit in $S_{\alpha} \cup S_{\beta}$ which implies that $\{H_{\alpha}, H_{\beta}, LU\}$ is universal on $S_{\alpha} \cup S_{\beta}$. $\square$

Lemma 3. *If H_{α} has odd parity, n , H_{β} has even parity, and $S_{\beta} \subset S_{\alpha}$, then $\{H_{\alpha}, H_{\beta}, LU\}$ is universal on S_{α} .*

Consider the following example. Let $H_\alpha = X^{\otimes 5}$ and $H_\beta = I^{\otimes 3} \otimes Y \otimes X$. The commutator of these Hamiltonians is a four-qubit coupling, and therefore, by Lemma 1, they are universal on S_α :

$$i[H_\alpha, H_\beta] = -2X \otimes X \otimes X \otimes Z \otimes I \quad (13)$$

Let's now generalize this example to prove Lemma 3.

Proof: Using H_α and LU we can simulate the Hamiltonian $X^{\otimes n}$, and by Lemma 2 H_β and LU can be used to simulate the Hamiltonian $I^{\otimes n-2} \otimes Y \otimes X$ (assuming we number the qubits so that the n^{th} and $(n-1)^{\text{th}}$ qubits are in S_α). Then we can simulate the Hamiltonian

$$i[X^{\otimes n}, I^{\otimes n-2} \otimes Y \otimes X] = -2X^{\otimes n-2} \otimes Z \otimes I, \quad (14)$$

which acts on $n-1$ qubits in S_α . Therefore, Lemma 1 implies that $\{H_\alpha, H_\beta, LU\}$ is universal on S_α . $\square$

Corollary 2. *If H_α has odd parity and we have a universal set of gates U_β acting on a set of qubits S_β such that $S_\beta \subset S_\alpha$ and $|S_\beta| > 1$, then the set $\{H_\alpha, U_\beta, LU\}$ is universal on S_α .*

A simple example of such a set of universal gates on three qubits is $\{X^{\otimes 3}, \text{CNOT} \otimes I, LU\}$.

Proof: If we have a universal set of gates U_β on S_β , then it is possible to simulate a unitary operator equivalent to a Hamiltonian evolution by H_γ acting on an even number of qubits $|S_\gamma|$ with $1 < |S_\gamma| \leq |S_\beta|$. Then by Lemma 3 the corollary is true. $\square$

Lemma 4. *If H_α has even parity, n , H_β has odd parity, m , and $S_\alpha \cap S_\beta \neq \emptyset$, then $\{H_\alpha, H_\beta, LU\}$ is universal on $S_\alpha \cup S_\beta$.*

Proof: First, consider the case where $|S_\alpha \cap S_\beta| = 1$. Label the qubits so that S_α contains the first n qubits from the left and S_β contains the first m qubits from the right. Thus $X^{\otimes n} \otimes I^{\otimes m-1} \in C_\alpha$ and $I^{\otimes n-1} \otimes Y^{\otimes m} \in C_\beta$. We can simulate the commutator

$$i[X^{\otimes n} \otimes I^{\otimes m-1}, I^{\otimes n-1} \otimes Y^{\otimes m}] = -2X^{\otimes n-1} \otimes Z \otimes Y^{\otimes m-1}. \quad (15)$$

Now, this commutator acts on $|S_\alpha \cup S_\beta| = m+n-1$ qubits which is an even number, and therefore by Lemma 2 this Hamiltonian and LU are universal on these qubits.

The case $|S_\alpha \cap S_\beta| > 1$ is even simpler to prove. Since n is even, H_α is universal on S_α by Lemma 2. Now, when $|S_\alpha \cap S_\beta| > 1$ we have a universal set of gates acting on $S_\alpha \cap S_\beta$, so Corollary 2 proves that we have a universal set on S_β , and therefore we have a universal set on $S_\alpha \cup S_\beta$. $\square$

Lemma 5. *If we have a universal set of gates U_α acting on S_α such that $|S_\alpha| \geq 2$, and H_β acting on S_β such that $S_\alpha \cap S_\beta \neq \emptyset$, then $\{U_\alpha, H_\beta, LU\}$ is universal on $S_\alpha \cup S_\beta$.*

Proof: The proof follows simply by considering the four possible parity combinations for $|S_\alpha|$ and $|S_\beta|$:

- **Case:** $|S_\alpha|$ even, $|S_\beta|$ odd. The result follows from Lemma 4.

- **Case:** $|S_\alpha|$ even, $|S_\beta|$ even. The result follows from Corollary 1.
- **Case:** $|S_\alpha|$ odd, $|S_\beta|$ even. The result follows from Lemma 4, with the roles of α and β interchanged.
- **Case:** $|S_\alpha|$ odd, $|S_\beta|$ odd. Pick an even parity subset S_{ev} of S_α which has a non-trivial overlap with S_β . Since we have universality on S_α we must also have universality on S_{ev} . Lemma 4 therefore implies universality on $S_{\text{ev}} \cup S_\beta$. Universality on $S_\alpha \cup S_\beta$ now follows from Theorem 1. $\square$

Lemma 5 gives us a composition rule for determining whether or not a Hamiltonian is universal on a given set of qubits. It tells us that if we have a set qubits coupled by even-parity coupling terms (and thus a universal set of gates on the set), then any other qubits that they are connected to, even indirectly, will also have a universal set defined on them. We will see from the following lemma that this is the only way a universal set of gates can be derived.

Lemma 6. *If H_α and H_β both have odd parity, then their commutator $H_\gamma = i[H_\alpha, H_\beta]$ is either 0 or it has odd parity.*

Proof: If $S_\alpha \cap S_\beta = \emptyset$ then $i[H_\alpha, H_\beta] = 0$, and the lemma is trivially true. In the case where $S_\alpha \cap S_\beta \neq \emptyset$ let $u = |S_\alpha \cap S_\beta|$. Now, $H_\gamma \neq 0$ only when $|S_\gamma \cap (S_\alpha \cap S_\beta)| = d$ is odd. By definition we find that $|S_\gamma| = |S_\alpha| + |S_\beta| - 2u + d$. Since $|S_\alpha| + |S_\beta|$ and $2u$ are even, but d is odd, $|S_\gamma|$ must be odd for any non-zero H_γ . $\square$

The conclusions of these lemmas can be succinctly expressed in the following theorem.

Theorem 2. *An entangling Hamiltonian acting on n qubits, together with local unitary operations, is dynamically universal if and only if the Pauli operator expansion of the Hamiltonian contains a term with an even number of entries.*

Proof: From Lemma 6 we know that an entangling Hamiltonian whose Pauli operator expansion contains only odd-parity terms, together with local unitaries, can only generate other odd-parity Hamiltonians, which shows that it is not universal. Conversely, from Lemmas 2 and 6, we see immediately that an entangling Hamiltonian with at least one even-parity term is universal. $\square$

We now know that in order for a general n -qubit Hamiltonian to be universal when aided by one-qubit unitaries, it must fulfill two conditions. The first condition is that the Hamiltonian must be entangling, in the sense explained in the introduction, i.e., all n qubits must be connected, either directly or indirectly, by coupling terms in the Hamiltonian. The second condition is that at least one of the coupling terms must have even parity. Thus, our result reduces the problem of determining when a Hamiltonian is universal to that of counting the parity of terms in its Pauli operator expansion.

Let's look at a couple of examples. It was suggested in the preprint version of [1] (but not the published version) that it might be possible to construct many-body Hamiltonians which are not universal by using results from the theory of entanglement. For example, the GHZ state $|GHZ\rangle = (|000\rangle + |111\rangle)/\sqrt{2}$ and W-state $(|001\rangle + |010\rangle + |100\rangle)/\sqrt{3}$ are distinct types of entanglement which cannot be interconverted [11], even stochastically, by local operations and classical communication. This led [1] to conjecture that Hamiltonians such as $H_{GHZ} = |GHZ\rangle\langle GHZ|$ and $H_{GHZ'} = |GHZ\rangle\langle 000| + |000\rangle\langle GHZ|$ are not universal, when assisted by local unitaries. This conjecture turns out to be incorrect. Expanding in the Pauli basis and omitting $\otimes$ for brevity, we obtain:

$$H_{GHZ} \propto III + ZZI + ZIZ + IZZ - XYY - YXY - YYX \quad (16)$$

$$H_{GHZ'} \propto III + ZII + IZI + IIZ + ZZI + ZIZ + IZZ + ZZZ - XXX. \quad (17)$$

In both cases, we simply check that each qubit is coupled by one of the two- or three-qubit terms, so the Hamiltonian is entangling, and note that there are terms with even parity, so by Theorem 2 both these Hamiltonians are universal when assisted by local unitaries.

V. HAMILTONIANS WITH ALL-ODD PARITY

In the previous section we showed that the only non-universal entangling Hamiltonians are the odd Hamiltonians, i.e., those whose couplings all act on an odd number of qubits. In this section we study what dynamical operations can be achieved using such Hamiltonians, together with local unitary operations. We prove two main results.

The first result is that an odd entangling Hamiltonian can be used to simulate any other odd Hamiltonian on the system of n qubits. This result, in combination with the results of the previous section, shows that there are essentially only two types of entangling Hamiltonian on n qubits: Hamiltonians that are odd, and those that are not. Within these two classes all the Hamiltonians are essentially inter-convertible, in the sense that any one can be used to simulate the other. Furthermore, the entangling Hamiltonians that are not odd are intrinsically more powerful than the odd Hamiltonians, since they can be used to simulate any odd Hamiltonian, but not vice versa.

The second result is to show that odd Hamiltonians can be made universal, by using an appropriate *logical basis* of qubits for our system, similar to the ideas used in quantum error-correction. In particular, we show that such an interaction on n qubits is universal on a set of $n-1$ logical qubits. In fact, we will see that the encoding is as simple as it could be: each of the $n-1$ logical qubits

corresponds directly to one of the original n qubits, while the single qubit left over is not used.

To obtain our results we first need a simple lemma allowing us to use an odd Hamiltonian coupling a set of qubits to generate odd Hamiltonians acting on a subset of those qubits.

Lemma 7. *If H_α has odd parity then we can simulate any other odd-parity Hamiltonian H_β provided $S_\beta \subseteq S_\alpha$.*

Proof: Let $|S_\alpha| \equiv 2m+1$. We prove this lemma using induction on m . The lemma is trivially true for the case $m=1$ (that is, $|S_\alpha|=3$). Now, we make the inductive assumption that the lemma holds for the m^{th} case and prove that it holds for the $(m+1)^{\text{th}}$ case. Given $H_{\alpha'}$ acting on a set of $|S_{\alpha'}|=2m+3$ qubits, we need only show that we can simulate a Hamiltonian acting on any subset of $S_{\alpha'}$ containing $2m+1$ qubits. By assumption, we can simulate the $(2m+3)$ -qubit Hamiltonians $X^{\otimes 2m+3}$ and $X^{\otimes 2} \otimes Y^{2m+1}$ and thus their commutator

$$i[X^{\otimes 2m+3}, X^{\otimes 2} \otimes Y^{2m+1}] = -2iI \otimes I \otimes (iZ)^{\otimes 2m+1}. \quad (18)$$

Therefore we can simulate a Hamiltonian acting on the final $2m+1$ qubits of S_α . Similarly, we can simulate a Hamiltonian acting on any subset of S_α containing $2m+1$ qubits, which proves the inductive hypothesis and thus the lemma. $\square$

It turns out that both the main results of this section are corollaries of this lemma and a second result that is motivated by the following example. Suppose we have the ability to simulate the odd Hamiltonian $H = ZZZII + IIZZZ$ (where we have omitted both subscripts and tensor products). We already know that we can therefore simulate $ZZZII$ and $IIZZZ$ separately. Suppose further that we wish to simulate another odd Hamiltonian, $ZIIZZ$. We can see that this is possible, using our intuition about non-odd Hamiltonians, by “isolating” one of the qubits, say the fifth qubit, and considering the Hamiltonians that we can simulate on the first four qubits. So, let's alter our example and give ourselves the ability to to perform $ZZZI$ and $IIZZ$ on the first four qubits, and we will attempt to simulate $ZIIZ$. Notice that now we have an odd and an even term that connect the first four qubits, so by Theorem 2, there must be a sequence of commutators and linear combinations that allow us to simulate $ZIIZ$. Here is such a sequence, where in each step we generate a new coupling to add to our set of allowed couplings:

$$\begin{aligned} i[ZZYI, IIXZ] &= 2ZZZZ, \\ i[XZXX, YZYY] &= 2ZIZZ, \\ i[ZIZY, IIZX] &= 2ZIIZ. \end{aligned} \quad (19)$$

Now, if we consider the original problem on five qubits, we see that the odd parity restriction shows that this procedure generates the desired coupling $ZIIZZ$:

$$\begin{aligned} i[ZZYII, IIXZZ] &= 2ZZZZZ, \\ i[XZXXX, YZYYZ] &= 2ZIZZI, \\ i[ZIZYI, IIZXZ] &= 2ZIIZZ. \end{aligned} \quad (20)$$

In a similar vein, suppose that we wish to simulate an even-parity coupling $ZIIZI$. We know that this is not possible directly (otherwise H would be dynamically universal), but it is possible using a very simple encoding. If we place the fifth qubit in the Z -eigenstate $|0\rangle$, then our procedure above for simulating $ZIIZZ$ allows us to simulate $ZIIZ$ on the first four qubits. Thus, H is dynamically universal on the first four qubits.

Our main results of this section generalize these two examples. Both examples rely crucially on the fact that there was a qubit that could be *isolated*, that is, acted on by only a single member of the set of couplings that we used to do our simulation. For example, suppose we tried to use the same approach to show that H can simulate $ZIIZ$ on four of the five qubits by placing the third qubit in the state $|0\rangle$. Then the two couplings that we have at our disposal on the remaining four qubits are $ZZII$ and $IIZZ$, which do not connect the four qubits, and thus cannot be universal on them. We formalize this intuition in the following lemma.

Lemma 8. *Let $H = \sum H_\alpha$ be an odd entangling n -qubit Hamiltonian, and $\mathcal{H} = \{H_\alpha\}$ be the set of all terms in H . Then there exists a set $\mathcal{M} \subseteq \mathcal{H}$ that (a) connects all n qubits in such a way that (b) at least one of the qubits is only acted on by a single element of $\mathcal{M}$. We call such a qubit an isolated qubit, and $\mathcal{M}$ an isolating set for that qubit.*

Proof: We prove this lemma by giving a constructive procedure to generate an appropriate set $\mathcal{M}$. For convenience, define $n_\alpha \equiv |S_\alpha|$ for all α .

1. Choose a term H_1 from the set $\mathcal{H}$. Without loss of generality, we may number the qubits so that it acts on the first n_1 qubits. Add H_1 to the set $\mathcal{M}$.
2. Search for a second term in the set $\mathcal{H}$ that overlaps with H_1 and also acts on at least one qubit outside of S_1 . If there is no such term, then H_1 must couple all of the qubits, in which case $\mathcal{M} = \{H_1\}$ satisfies the conditions above and we are done.
3. Otherwise, choose such a term and call it $H_{2'}$. Define $n_{S_1 \cap S_{2'}}$ to be the number of qubits in $S_1 \cap S_{2'}$. Without loss of generality, we may assume that these qubits are strung out in a line, with the n_1 left-most qubits in S_1 and the $n_{2'}$ right-most qubits in $S_{2'}$, and the $n_{S_1 \cap S_{2'}}$ overlapping qubits in the middle.
4. If $n_{S_1 \cap S_{2'}}$ is odd, then use $H_{2'}$ to simulate a Hamiltonian H_2 that acts on qubits $n_1, \dots, n_1 + n_{2'} - n_{S_1 \cap S_{2'}}$ (where we number from the left, starting at 1). H_2 acts on the right-most $n_2 \equiv n_{2'} - n_{S_1 \cap S_{2'}} + 1$ qubits, overlapping with H_1 on just a single qubit (the n_1 th qubit). This is possible since n_2 is odd and $S_2 \subseteq S_{2'}$, satisfying the conditions of Lemma 7. Add H_2 to $\mathcal{M}$.

5. On the other hand, if $n_{S_1 \cap S_{2'}}$ is even, then we use $H_{2'}$ to simulate a Hamiltonian H_2 that acts on qubits $n_1 - 1, \dots, n_1 + n_{2'} - n_{S_1 \cap S_{2'}}$. This H_2 acts on the right-most $n_2 \equiv n_{2'} - n_{S_1 \cap S_{2'}} + 2$ qubits, overlapping with H_1 on just two qubits, in positions $n_1 - 1$ and n_1 . Again, n_2 is odd and $S_2 \subseteq S_{2'}$, satisfying the conditions of Lemma 7. Add H_2 to $\mathcal{M}$.
6. Now, if there are no other terms that overlap H_2 , then the right-most qubit in S_2 must be isolated since H_2 acts on at least three qubits, and overlaps with H_1 on at most two. If we then add the remaining Hamiltonians from $\mathcal{H}$ (i.e., all except for H_1 and $H_{2'}$) to $\mathcal{M}$, then $\mathcal{M}$ must couple all n qubits and contain an isolated qubit, satisfying the conditions above, and so we are done.
7. Otherwise, repeat steps 2 to 5 to generate a Hamiltonian H_3 that overlaps only with H_2 on one or two qubits, and add it to $\mathcal{M}$. Repeat this process, adding a Hamiltonian to $\mathcal{M}$ each time, until it becomes impossible to find a term that both overlaps with the previous term and acts on at least one more qubit than it. When the process terminates (which must happen eventually since there is only a finite number of qubits), the last term that was added must contain an isolated qubit. If $\mathcal{M}$ connects all n qubits then we are done, otherwise add the remaining Hamiltonians from $\mathcal{H}$ to $\mathcal{M}$ to complete the construction.

□

Using this lemma, we can prove our two main results.

Theorem 3. *Let H be an odd n -qubit entangling Hamiltonian. Then H and LU can simulate any odd Hamiltonian on the n qubits.*

Proof: Let $\mathcal{M}$ be an isolating set for a qubit, which, without loss of generality, we may choose to be the n^{th} qubit. Suppose we consider the set of couplings $\mathcal{M}'$ on the first $n - 1$ qubits that arises by simply taking the couplings in $\mathcal{M}$, and omitting the Pauli acting on the final qubit. Then by construction of $\mathcal{M}$ we see that this set (a) connects the first $n - 1$ qubits, and (b) contains an element that acts on an even number of these qubits, corresponding to the element of $\mathcal{M}$ that couples to the isolated qubit. By Theorem 2 it follows that $\mathcal{M}'$, together with local unitaries, is universal on the first $n - 1$ qubits.

Lifting back up to the full set of n qubits, we see that $\mathcal{M}$ must generate the set of all odd couplings on the n qubits. To see this a little more explicitly, suppose that we wish to generate an odd coupling σ . Let σ' be the corresponding coupling on the first $n - 1$ qubits. By an appropriate sequence of commutators of elements of $\mathcal{M}'$ we can generate σ' . The corresponding sequence of commutators in $\mathcal{M}$ must generate σ , up to possible relabeling on the final qubit, which can be accomplished via appropriate local unitaries. □

Theorem 4. *Let H be an odd n -qubit entangling Hamiltonian. Then H and LU are universal on a set of $n - 1$ logical qubits.*

Before proving this theorem, let's consider another example. Consider the Hamiltonian $H_\alpha = Z \otimes Z \otimes Z$. We know from the previous section that this Hamiltonian and local unitaries do not form a universal set of operations on three qubits. However, if we prepare the third qubit in the $|0\rangle$ eigenstate of Z at the beginning of the procedure, then any succession of evolutions of H_α and local unitaries acting only on the first two qubits will leave the third qubit invariant throughout the evolution. So if, for instance, we trace over the third qubit we find that the reduced system evolves according to $Z \otimes Z$. We know that this Hamiltonian is universal on the reduced system, so in effect we have a universal set of gates on the first two qubits. Essential to this example is our ability to identify a qubit that can be prepared in a local eigenstate of the Hamiltonian that entangles the other qubits.

Proof: The proof is simply to number the qubits $1, \dots, n$, and to prepare the n^{th} qubit in a fixed state $|0\rangle$. Suppose now that we wish to simulate an arbitrary Pauli σ acting on the first $n - 1$ qubits. If σ has odd parity, then we can use the results of Theorem 3 to simulate σ directly. If σ has even parity then we use the results of Theorem 3 to simulate $\sigma \otimes Z$, which leaves the state of the final qubit unchanged, and evolves the first $n - 1$ qubits according to the Hamiltonian σ . Thus, we can use this construction to simulate any interaction on the first $n - 1$ qubits. $\square$

We now understand that odd n -qubit Hamiltonians, in contrast to the non-odd Hamiltonians, do not generate the algebra $\mathfrak{su}(2^n)$. What algebra do they generate?¹ It turns out that the answer depends on whether n is odd or even.

To state and prove our results, it is helpful to be a little more precise about the various Lie algebras we are considering. We define $\mathfrak{g}$ to be the real Lie algebra generated by odd parity Paulis acting on n qubits. More precisely, $\mathfrak{g}$ is a real vector space whose basis elements are of the form $i\sigma$, where σ is an odd parity Pauli. We have shown that this is the relevant Lie algebra associated with an entangling Hamiltonian on n qubits, plus one-qubit unitaries. The following theorem relates $\mathfrak{g}$ to the standard classification of Lie algebras:

Theorem 5. *If n is even, then $\mathfrak{g}$ is isomorphic to $\mathfrak{so}(2^n)$. If n is odd, then $\mathfrak{g}$ is isomorphic to $\mathfrak{sp}(2^n)$. Furthermore the representation of $\mathfrak{g}$ provided by tensor products of odd parity Paulis on n qubits is the fundamental (defining) representation of these Lie algebras.*

Amusingly, the $n = 2$ case of this theorem is a well-known result from Lie theory, the isomorphism between

$\mathfrak{so}(4)$ and $\mathfrak{su}(2) \otimes \mathfrak{su}(2)$. This result has received wide use in quantum information theory in a different guise — it is just the fact that local (special) unitary operations on two qubits correspond to real orthogonal transformations in the so-called “magic basis”.

Proof: We consider the n even case first. Let us define an operation $f(\sigma) \equiv (-1)^{\text{wt}(\sigma)}\sigma$ on Pauli matrices, where $\text{wt}(\sigma)$ is the weight of σ . This operation can be extended by linearity to all matrices. Observe that:

$$f(A) = Y^{\otimes n} A^T Y^{\otimes n}. \quad (21)$$

Then the Lie algebra $\mathfrak{g}$ consists of all matrices A such that:

$$f(A) = -A, \quad \text{and} \quad A^\dagger = -A. \quad (22)$$

The Lie algebra $\mathfrak{so}(2^n)$ can be defined similarly. Recall that the defining representation of the Lie algebra $\mathfrak{so}(2^n)$ consists of $2^n \times 2^n$ matrices B which satisfy [25, 26]

$$B^T = -B, \quad \text{and} \quad B^\dagger = -B, \quad (23)$$

where T denotes the transpose operation.

We aim to find a unitary U such that B satisfies Eq. (23) if and only if $A = UBU^\dagger$ satisfies Eq. (22). It is easy to see that for any U , $A^\dagger = -A$ if and only if $B^\dagger = -B$, so we need only find a U such that $f(A) = -A$ if and only if $B^T = -B$. Straightforward algebraic manipulation shows that $U = (I - iY^{\otimes n})/\sqrt{2}$ satisfies this requirement.

The n odd case is very similar. The defining representation of the Lie algebra $\mathfrak{sp}(2^n)$ consists of $2^n \times 2^n$ matrices which satisfy [25, 26]

$$J^\dagger B^T J = -B, \quad \text{and} \quad B^\dagger = -B, \quad (24)$$

where $J = Y_1 \otimes I$ is the Pauli Y acting on the first qubit alone. Setting $U = I \otimes (I - iY^{\otimes n-1})/\sqrt{2}$, we see that Eq. (24) is equivalent to Eq. (22) if we set $A = UBU^\dagger$. $\square$

An interesting consequence of Theorem 5 occurs for odd parity Paulis acting on an odd number of qubits, n . Suppose we are given some known pure state, $|\psi\rangle$. We can then ask the question of whether we can transform this state into any other state, $|\phi\rangle$. Clearly if we have control over $\mathfrak{su}(2^n)$ we can perform this task. A theorem from the study of the controllability of quantum systems [27, 28] shows that this task can be performed for all states $|\psi\rangle$ and $|\phi\rangle$ if and only if one has control over the Lie algebra $\mathfrak{su}(2^n)$ or the Lie algebra $\mathfrak{sp}(2^n)$. Thus, while we do not have full unitary control when we have odd parity Paulis acting on an odd number of qubits (except when $n = 1$), we can transform any state into any other state using these operations.

VI. EFFICIENCY

We have examined the problem of Hamiltonian simulation across sets of qubits that are coupled by a fixed

¹ This question was originally posed to us by Greg Kuperberg.

natural Hamiltonian. However, our results appear to be limited by the fact that our simulation techniques are manifestly exponential in the total number of qubits n . The problem is that our procedure for isolating a single term of an arbitrary Hamiltonian requires on the order of 2^n local unitaries to be interspersed in the evolution at different times (see equation (7)). This is in sharp contrast to the case of Hamiltonians whose Pauli expansions contain only two-qudit couplings, and simulation techniques are polynomial in the number of qudits. This defect could be fixed if we were to find efficient techniques for term isolation, for all other steps in our procedure were efficient, at least in principle.

It is not surprising that, in this very general situation, we have not obtained efficient simulation techniques. Suppose, for example, that we have a family of Hamiltonians that has the property that the member of the family that acts on n qubits has a decomposition containing a tensor product of X s acting on every subset of those n qubits:

$$\begin{aligned} H_{(2)} &= X_1 X_2 \\ H_{(3)} &= X_1 X_2 + X_1 X_3 + X_2 X_3 + X_1 X_2 X_3 \\ H_{(4)} &= X_1 X_2 + \cdots + X_1 X_2 X_3 + \cdots + X_1 X_2 X_3 X_4 \\ &\vdots \end{aligned} \tag{25}$$

where the subscripts in brackets indicate the number of qubits acted on by each Hamiltonian. These Hamiltonians are not at all natural since every possible coupling of qubits is represented, regardless of how “far away” the qubits are from one another. With such a large number of couplings ($2^n - n - 1$ for the n -qubit member of the family), it is not surprising that we have not found a method to efficiently simulate a set of gates that is universal for quantum computation, since it is difficult to “turn off” enough unwanted interactions, while retaining computational universality, even though these Hamiltonians are dynamically universal. As mentioned in the introduction, we conjecture that a generic entangling Hamiltonians will not be universal for quantum computation.

On the other hand, it would be surprising if the following family of Hamiltonians could not be used simulate a universal set of gates:

$$\begin{aligned} H_{(2)} &= X_1 X_2 \\ H_{(3)} &= X_1 X_2 + X_2 X_3 + X_1 X_2 X_3 \\ H_{(4)} &= X_1 X_2 + X_2 X_3 + X_3 X_4 + X_1 X_2 X_3 + X_2 X_3 X_4 \\ H_{(5)} &= X_1 X_2 + \cdots + X_4 X_5 + X_1 X_2 X_3 + \cdots + X_3 X_4 X_5 \\ &\vdots \end{aligned} \tag{26}$$

In these Hamiltonians, each qubit is directly coupled to at most four other qubits by terms acting on at most three qubits. For example, qubit 3 only ever couples directly to qubits 1, 2, 4, and 5. Furthermore, the number

of coupling terms is linear in the number of qubits — the Hamiltonian on n qubits has only $2n - 3$ terms in its decomposition. This number is sufficiently small, by contrast with the general case, that we might hope that it is possible to turn off most (but not all) of these couplings in an efficient fashion. We call a Hamiltonian (or, more precisely, a family of Hamiltonians) k -local if the maximum number of qubits coupled by any term in its decomposition is k and if the absolute values of the non-zero coefficients multiplying each coupling in H (the $h_{j_1, \dots, j_n}$ in the expansion of H in equation (2)) are bounded below by a constant. This family of Hamiltonians is thus 3-local.

Motivated by these examples, we now describe a randomized algorithm which shows that a single term in a k -local Hamiltonian can be isolated with high probability in a number of steps that is exponential in k but polynomial in n . Thus, given a family of k -local Hamiltonians, for some fixed k , we have a procedure to efficiently simulate a set of gates that is universal for quantum computation.

More precisely, suppose we wish to isolate a single term H_α in the expansion of H using local unitaries. We give a procedure to use a randomly chosen set of local unitaries $\{U_j\}$ to isolate H_α with failure probability bounded above by $N/2^m$, where N is an upper bound on the number of terms in H and m is the number of local unitaries in the set $\{U_j\}$.

If H is k -local, then N is polynomial in n — a simple bound on N is n^k — and hence the probability of failure is polynomial in n and decreases exponentially in the number of local unitaries. More precisely, to bound the probability of failure to be less than ϵ , it turns out to be sufficient to choose $m \geq \log(N/\epsilon)$. The number of timesteps required increases by a factor of two for each extra unitary, so the number of timesteps is bounded above by $2^m = N/\epsilon$. Provided N is a polynomial function of n , as is the case if H is k -local, the number of timesteps is also polynomial in n .

Algorithm: To explain the algorithm, we begin by explaining how to eliminate a single unwanted term from H , without worrying about keeping our desired term. (We will see later that a simple modification of this procedure eliminates the unwanted term and keeps the desired term.) Suppose, without loss of generality, that the unwanted term has the form $H_\beta = Z_1 Z_2 \cdots Z_l I_{l+1} \cdots I_n$. In order to eliminate this term, we choose a set of local unitaries $\{U_j\}$, each of which is a tensor product of n unitaries each chosen independently with equal probability from the set $\{I, X, Y, Z\}$. We then do the following conjugations:

$$\begin{aligned} H^{(1)} &= U_1 H U_1 + H, \\ H^{(2)} &= U_2 H^{(1)} U_2 + H^{(1)}, \\ &\vdots \\ H^{(m)} &= U_m H^{(m-1)} U_m + H^{(m-1)} \end{aligned} \tag{27}$$

The probability that $H^{(m)}$ still contains the unwanted

term H_β is the probability that each U_j commutes with H_β . The probability that a particular U_j commutes with H_β is simply the probability that the total number of X and Y terms in U_j that act on the first l qubits is even. So, if l is 1, then the probability that U_j commutes with $H_\beta = Z_1$ is just the probability that U_j has a Z or an I on the first qubit, which is $1/2$. Similarly, if H_β acts nontrivially on the first 2 qubits, then the probability that U_j commutes with it is the probability that its first two terms are I_1I_2 , Z_1Z_2 , X_1X_2 , X_1Y_2 , X_1Z_2 , Y_1X_2 , Y_1Y_2 , or Y_1Z_2 , which is again $1/2$. It is not hard to see that this pattern holds for any choice of H_β — the probability that it commutes with a randomly chosen U_j is always $1/2$. Thus, the probability that all m of the U_j commute with H_β is simply $1/2^m$.

Now impose the constraint that we wish to keep a particular term H_α while eliminating H_β in this way. Instead of choosing U_j completely randomly, we instead generate a random product of Paulis, and then check to see if it commutes with our desired term, H_α . If it does, which happens with probability $\frac{1}{2}$, then we add it to the set $\{U_j\}$, otherwise we repeat the process. A simple case analysis now shows that the probability of a given U_j in this set commuting with H_β is $\frac{1}{2}$. Thus, the probability that all m of the U_j chosen in this fashion commute with H_β is again $1/2^m$.

In general there will be many terms in the expansion of H that we wish to eliminate while isolating H_α . The probability that $H^{(m)}$ contains a term other than H_α (i.e., our procedure has failed) is certainly no greater than the sum of the probabilities that the procedure failed to eliminate each term H_β , that is $N/2^m$ where N is the number of terms in H that must be eliminated. $\square$

VII. SUMMARY AND FUTURE DIRECTIONS

We have examined the problem of simulating Hamiltonians using a fixed multi-qubit Hamiltonian and local unitary operations. We have provided a classification

scheme for the simulations that are possible given these resources. In particular, we have demonstrated that there are only two physically distinct classes of entangling Hamiltonians up to local unitary operations. One class, the class of odd entangling Hamiltonians, when assisted by local unitary operations, can simulate all odd Hamiltonians but nothing else. The other class, the class of non-odd entangling Hamiltonians, can simulate all Hamiltonians and are thus dynamically universal. We have also demonstrated that all odd entangling Hamiltonians can be made universal through the use of a simple encoding scheme. Furthermore, the Lie algebras generated by the odd entangling Hamiltonians together with local unitary operations were shown to be isomorphic to either $\mathfrak{so}(2^n)$ or $\mathfrak{sp}(2^n)$, depending on whether n is even, or odd, respectively.

In this paper we have made a distinction between sets of resources that are universal for quantum computation and those that are dynamically universal. This distinction has been necessary because we can not find an efficient means to simulate the Hamiltonians used in quantum computation with an arbitrary fixed entangling Hamiltonian and local unitaries. We have demonstrated that when restricted to k -local Hamiltonians with lower-bounded coefficients dynamic universality is equivalent to universality for quantum computation. The resolution of when this equivalence holds in general would be an interesting contribution to the study of quantum dynamics.
